Thick deposits cover broad regions of the Martian mid-latitudes with a smooth mantle; erosion in these regions creates scarps that expose the internal structure of the mantle. We investigated eight of these locations and found that they expose deposits of water ice that can be >100 meters thick, extending downward from depths as shallow as 1 to 2 meters below the surface. The scarps are actively retreating because of sublimation of the exposed water ice. The ice deposits likely originated as snowfall during Mars' high-obliquity periods and have now compacted into massive, fractured, and layered ice. We expect the vertical structure of Martian ice-rich deposits to preserve a record of ice deposition and past climate.

One-third of the Martian surface contains shallow ground ice. This ice is a critical target for science and exploration: it affects modern geomorphology, is expected to preserve a record of climate history, influences the planet's habitability, and may be a potential resource for future exploration. The extent of Martian ground ice and the depth to the ice table have been predicted in theory (1–3) and have been tested both in situ (4) and from orbital observations (5–17). However, the vertical structure of subsurface ice remains poorly known, including its layering, thickness, and purity, which record its emplacement and subsequent modification processes. Information about the structure, depth, and purity of shallow ice is also required to plan possible in situ resource utilization (ISRU) on future missions (18).

Early theoretical predictions suggested that Martian subsurface ice would be ice-cemented ground (1). Orbital neutron-spectrometer data have revealed ice contents greater than the likely pore space volume in the upper few centimeters of the ice table in many locations (5–7). Shallow ice (<1 to 2 m) exposed by fresh impacts remains distinct for months or years, also indicating a low rock or dust content, although possibly modified by the impact process (8, 10, 13). The Phoenix lander on the northern plains uncovered both ice-cemented regolith and deposits of pure (>99 vol-

ume %) ice (4, 14) at a few centimeters depth. The ice at that site likely extends to 9 to 66 m depth on the basis of shadow radar reflections (15), but geomorphic interpretations suggest that ice-cemented ground is dominant there (16). However, ice-loss landforms indicate that several regions on Mars have high ice volume fractions extending through substantial subsurface depths (17, 18), and radar echo power data have suggested high ice contents beneath areas of the northern plains (6). Subsurface radar reflections indicate the presence of debris-covered glaciers (19, 20) as well as buried regional ice sheets in the Utopia and Arcadia Planitia regions that are up to 170 m thick and nearly pure ice (21, 22). Because the radar did not resolve the top of the ice, it is likely to be within ~20 m of the surface, the limit of the radar instrument's ability to iden-

tify shallow signals (23). The smaller-scale structure of the ice sheets and rocky cover are unresolved with current radar data. It remains unknown whether the ice within a few meters of the surface has the same origin and age as the deeper ice because the upper ice is most readily modified and best coupled to the recent climate.

We describe observations of the vertical structure of ground ice using the Mars Reconnaissance Orbiter (MRO). The observations target eight locations that have steep, pole-facing scarps created by erosion (Figs. 1 and 2 and figs. S1 to S3) in images from the High-Resolution Imaging Science Experiment (HiRISE); seven are located in the southern hemisphere, and the eighth location is a cluster of scarps in Milanković Crater in the north (table S1). Each of the scarps is relatively blue (compared with surrounding terrain) in enhanced-color HiRISE images, and three locations have water-ice signatures in mid-summer spectral data (Fig. 3 and figs. S4 and S5) taken by MRO's Compact Reconnaissance Imaging Spectrometer for Mars (CRISM) (24). CRISM spectra show an H₂O ice absorption feature at 1- μ m wavelength (fig. S6), which can be masked by as little as 1% soil (24). Tens of micrometers of dust are needed to make an opaque cover (24), so the dust content is low and/or wind removes dust.

Several lines of evidence indicate that the scarps are exposures of subsurface ice rather than persistent seasonal frost. First, they remain distinct from the surrounding terrain in color in all HiRISE images, including many observations acquired long after seasonal frost has sublimated from steep pole-facing slopes at higher latitudes. Second, Mars Odyssey Thermal Emission Imaging System (THEMIS) observations indicate late-afternoon scarp temperatures above the likely atmospheric frost point (25). Last, nearby pits lack relatively blue material that would be expected for topographically controlled frost (fig. S7).

The units hosting the scarps drap the terrain, with some meter-scale boulders on the surface
